Python for Math and Stat Fall 2023
Final Exam

Assume that all necessary packages have been imported.

1. (15 pts) For the following 4 problems, write down what each code block would display if executed in a Jupyter cell. If the code generates an error or infinite loop, write `Error`. Assume

```
arr = np.array([[10,  1,  9,  7, 12],
                [ 3, 16,  5,  8,  9]])
```

   (a)
```
arr[1, 4:0:-2]
```

   (b)
```
arr[arr > 9]
```

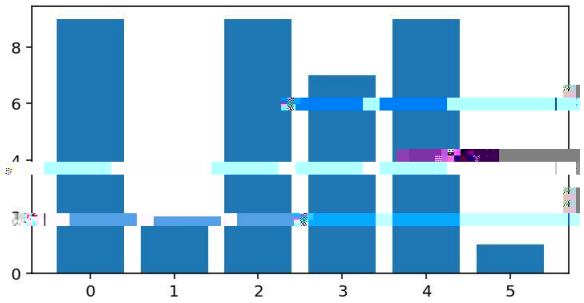
   (c)
```
kvals = {k: k*k for k in range(10)}
kvals[kvals[2]]
```

   (d)
```
def func(nums):
    print(nums, end=' ')
    if len(nums) == 1:
        return 10
    else:
        return func(nums[1:]) + 4

vals = [-5, 6, 2]
func(vals)
```

2. (8 pts) Write a function `plot_digits(num)` that plots the digits of a positive integer as a bar chart. It does not return a value. Use `try except` to catch invalid input, in which case no plot is created; `Error` is displayed instead.

   Examples:
   `plot_digits('abc')` displays `Error`.
   `plot_digits(929791)` produces the following result:



3. (10 pts) To check for errors when scanning or manually entering product bar codes, an extra check digit is included.

Here is a procedure for calculating the check digit for an integer code: (ex: 15694)

- Add every other digit in the code, starting with the first digit. (ex: 1 5 6 9 4: 1 + 6 + 4 = 11)
- Add every other digit in the code, starting with the second digit. (ex: 1 5 6 9 4 : 5 + 9 = 14)
- Add the second sum to 3 times the first sum. (ex: 14 + 3 11 = 47)
- The units digit of the result is the check digit. (ex: 7)

Write a function `check_digit(code)` that takes an integer `code` greater than 9 and returns its check digit as an `int`. For example, `check_digit(15694)` returns 7.

4. (10 pts) Consider the polynomial

$$P(x) = 1 + 2x + 3x^2 + 4x^3 + \quad + nx^{n\ 1}:$$

Write a function `poly_eval(x, n)` that calculates the value of $P(x)$ given values for x and positive integer n. Use **numpy** features (such as `arange` and vectorization). *Do not* include a loop.

Example: `poly_eval(2, 3)` returns 17 which equals $1 + 2(2) + 3(2)^2$.

5. (12 pts) The DataFrame `dfcocoa`, shown below, contains information about various cocoa powder products. Each row provides the name, weight (in ounces), and price (in dollars) for a distinct product.

Write code to do the following:

(a) Add a new `Nestle` product to the DataFrame with a weight of 8 ounces and a price of 2.75 dollars.

(b) Add a new column to the DataFrame called `UnitPrice` which equals the price per ounce for each product.

(c) Select the names of all products with a `UnitPrice` greater than the unit price for `Hersheys` (which is a product in `dfcocoa`). The result should be a pandas index or a list of strings.

(d) One of the products has the lowest unit price. Identify the name of that product as a string.

6. (20 pts) Create a class called `Coin`. Each instance of the class represents a coin with one attribute:

   - `prob_H`: probability of flipping a head. Assume that `prob_H` is a value between 0 and 1. Set the **default** value to 0.5.

   and these methods:

   - `flip()`: returns `'H'` or `'T'` given probability `prob_H`. (For example, if `prob_H` equals 0.2, then out of 100 flips, `'H'` will appear about 20 times.)
   - `flip_until(outcome)`: simulates the flipping of the coin, printing the results in a row, until the desired outcome appears. Return the number of flips. Assume that `outcome` is either `'H'` or `'T'`. This method should call `flip()`.

     Example: `flip_until('T')` might print HHHHT and return 5.
